(Received 14 April 1992; accepted for publication 19 June 1992)

The irreversible strain limit $\varepsilon_{\text{irrev}}$ for the onset of permanent axial strain damage to Ag-sheathed Bi$_2$Sr$_2$Ca$_2$Cu$_2$O$_{8+\delta}$ and Bi$_2$Sr$_2$Ca$_2$Cu$_3$O$_{10+\delta}$ superconductors has been measured to be in the range of 0.2%–0.35%. This strain damage onset is about an order of magnitude higher than for bulk sintered Y-, Bi-, or Tl-based superconductors and is approaching practical values for magnet design. The measurements show that the value of $\varepsilon_{\text{irrev}}$ is not dependent on magnetic field, nor does the critical current depend on strain below $\varepsilon_{\text{irrev}}$ at least up to 25 T at 4.2 K. Both of these factors indicate that the observed strain effect in Ag-sheathed Bi-based superconductors is not intrinsic to the superconductor material. Rather, the effect is extrinsic and arises from superconductor fracture. Thus, the damage onset is amenable to further enhancement. Indeed, the data suggest that subdividing the superconductor into fine filaments or adding Ag to the superconductor powder prior to processing significantly enhances the damage threshold $\varepsilon_{\text{irrev}}$ to above 0.6%.

Superconductor magnet applications subject the conductor winding to hoop strain typically on the order of 0.2%. For a safety factor of 2, the superconductor must therefore have a minimum axial strain tolerance of about 0.4% strain. Bulk sintered YBa$_2$Cu$_3$O$_7$ superconductors, unfortunately, fracture at a strain of only ~0.05%. Strain tolerance about an order of magnitude greater than this is needed for high $T_c$ superconductors to be used in practical magnet applications.

Here we present critical-current measurements of the effect of uniaxial-strain applied along the conductor axis of Ag-sheathed Bi$_2$Sr$_2$Ca$_2$Cu$_2$O$_{8+\delta}$ [Bi(2212)] and Bi$_2$Sr$_2$Ca$_2$Cu$_3$O$_{10+\delta}$ [Bi(2223)] high $T_c$ superconductors, both textured and untextured. These results show the irreversible strain limit $\varepsilon_{\text{irrev}}$ for the onset of magnetic critical-current degradation is about an order of magnitude greater than that of bulk-sintered superconductors. Furthermore, we observe no intrinsic elastic strain effect in Bi(2212) or Bi(2223) at 4.2 K, as evidenced by the lack of any measurable change in critical current density $J_c$ with strain below $\varepsilon_{\text{irrev}}$ at magnetic fields up to 25 T. The data also indicate that further improvement in $\varepsilon_{\text{irrev}}$ can be obtained by subdividing the superconductor material into fine filaments and by adding Ag to the superconductor powder prior to processing.

Results for three samples fabricated by different techniques are presented, representing both Bi(2212) and Bi(2223) crystal structures. Sample fabrication information is given in Table I. The first sample was a monocore Bi(2212) wire made by melt processing. This sample was a high-$J_c$ sample, but not necessarily optimized for strain tolerance and had in the core about a 30% void, which could well be a significant source of crack initiation sites. The second sample was a 19 filament Bi(2223) sample, which we tested to see the effect of subdividing the superconductor into filaments, as well as whether there were any significant electromechanical differences between the Bi(2212) and Bi(2223) compounds. The third sample was a Bi(2223) conductor having a dispersion of Ag in the superconducting matrix. The Ag particles were roughly equiaxed and about 5 μm in diameter; the Bi(2223) had the usual platelike structure, but the texturing was not nearly as high as that reported by Sato et al. or Tagano et al.

The apparatus for determining the effect of uniaxial strain up to 25 T was described earlier. The critical current was measured with an accuracy of about ±2% and critical current density $J_c$ was calculated based on the area of superconductor (not including the Ag sheath). The magnetic field was oriented perpendicular to the conductor axis (along which current and strain were applied) and in the plane of the tape samples.

The offset criterion was used to determine the critical-current density $J_c$ using a criterion value of either 1 or 1.5 μV/mm (the difference in the $J_c$ for the two criteria values is negligible using the offset method). The offset criterion is essential for the Ag-sheathed Bi conductors because of high normal-current conduction through the Ag sheath and the linear $V-I$ curve generated at strain-induced weak superconducting elements.

links. In such case, the \( V\)-\( I \) characteristic acquires a low-sloped linear rise. The offset criterion is a simple procedure that corrects for this normal (ohmic) conduction by taking the tangent to the \( V\)-\( I \) characteristic at \( E_c \) and extrapolating to \( V=0 \). The offset criterion is not very sensitive to the choice of criterion \( E_c \) since in the ohmic limit, it is completely independent of where the point of tangency is taken.

The mechanical data for this melt-processed monocore sample represent a worst-case because of the large void volume in the core that can act as a source of crack initiation sites. Even so, the increased strain tolerance over bulk-sintered materials is impressive; \( \epsilon_{\text{irrev}} \) is more than 4 times greater. Beyond \( \epsilon_{\text{irrev}} \), \( J_c \) falls to half its original value at about 0.38% strain (\( \epsilon_{0.5} \)), which is more than 7 times the comparable strain limit in typical bulk-sintered samples.

For these materials, there is no change in \( J_c \) for strain less than \( \epsilon_{\text{irrev}} \) even at 25 T. This suggests that the \( J_c \) degradation arises from superconductor fracture, rather than an intrinsic uniaxial-strain degradation of the superconductor energy gap, as with the A-15 and Chevrel superconductors. (This does not rule out any intrinsic strain effect, however, since these results were obtained well away from the critical temperature and upper critical field of these Bi-based superconductors.) Furthermore, as seen in Fig. 1, there is no magnetic-field dependence to \( \epsilon_{\text{irrev}} \).

A microscopic examination of the Ag/Bi(2212) interface in the powder-in-tube conductor is shown in Fig. 2 after the conductor had been strained over 1% at 4.2 K. The micrograph indicates that the Ag/Bi(2212) interface is intact, with no obvious shearing or delamination. There is, however, a series of transverse cracks distributed along the length of the Bi(2212) core, as seen in Fig. 2.

Figure 3 shows the \( J_c\)-\( E \) characteristic for the 19-filament Bi\(_{2}\)Sr\(_{2}\)Ca\(_{2}\)Cu\(_{2}\)O\(_{8}+\) conductor. The irreversible strain limit \( \epsilon_{\text{irrev}} \) is about 0.32%, more than 6 times that of bulk-sintered YBa\(_2\)Cu\(_3\)O\(_7\). Again there is no field dependence to \( \epsilon_{\text{irrev}} \) and no elastic strain effect is observed below \( \epsilon_{\text{irrev}} \) even at magnetic fields up to 20 T. The only effect is the irreversibility of the \( J_c\)-\( E \) curve above \( \epsilon_{\text{irrev}} \), which results from superconducting fracture. Thus, the primary parameter characterizing the electromechanical properties of these high \( T_c \) conductors at low temperature is simply the irreversible strain \( \epsilon_{\text{irrev}} \).
FIG. 2. Micrograph of sample 1, showing a series of cracks transverse to the Bi$_2$Sr$_2$Ca$_2$Cu$_3$O$_{10+x}$ core after the conductor had been strained 1% at 4.2 K.

The extrinsic nature of the effect is fortunate since it affords the possibility of improving $\varepsilon_{\text{rev}}$ through different processing. Indeed, one method for enhancing the mechanical properties is to subdivide the superconducting material into fine filaments and embed them in a ductile matrix to fill crack initiation sites at the surface of the filament. This is a technique that has worked well in the past for enhancing $\varepsilon_{\text{rev}}$ in the brittle, low $T_c$ superconductors. Some evidence for this is seen in the enhanced $\varepsilon_{\text{rev}}$ value for the multifilamentary sample 2. Another potential method is to coprocess the Bi powder compound with Ag powder to provide a ductile matrix within the superconductor core. The Ag matrix serves as a crack arrester and provides a region of plastic flow to relieve some of the stress.

Figure 4 shows the improved mechanical results for an experimental conductor employing the second technique. Although $J_c$ is not particularly high, the results for the monocore conductor, given in Fig. 4, show that $\varepsilon_{\text{rev}}$ can be increased to about 0.6% by adding 20 vol % Ag to the powder core, even without subdividing the superconductor material into fine filaments. The results in Figs. 3 and 4 at least indicate the potential of using these two techniques for significantly enhancing $\varepsilon_{\text{rev}}$ in high $T_c$ superconductors.

We are grateful to N. Bergren and C. C. Clickner for help in preparing the contacts and sample mount, S. L. Bray for assisting with one of the sample measurements, and G. A. Reinacker and C. Lutgen for help with data analysis. We also appreciate discussions with S. Bray, S. Sanders, and L. Goodrich. These data were obtained using the high-field magnet facilities of the Francis Bitter National Magnet Laboratory. J.W.F. was supported by the NIST high-$T_c$ program, DOD, and DOE. D.K.F. was supported by the DOE/BES.

FIG. 4. Axial strain dependence of $J_c$ for sample 3—an experimental monocore Bi$_2$Sr$_2$Ca$_2$Cu$_3$O$_{10+x}$ conductor with a 20 vol % Ag dispersion in the Bi core. $\varepsilon_{\text{rev}}$ was 0.6%, independent of magnetic field. Data points plotted with a + symbol (labeled by primed letters) denote $J_c$ determined after unloading from the data point labeled by the corresponding unprimed letter. Magnetic field was parallel to the tape surface.

FIG. 3. Axial strain dependence of $J_c$ for sample 2—a 19-filament, Ag-sheathed Bi$_2$Pb$_{0.6}$Sr$_{1.4}$Ca$_2$Cu$_3$O$_{10+x}$ superconductor, showing a field-independent $\varepsilon_{\text{rev}}$ of 0.32%. Data points plotted with a + symbol (labeled by primed letters) denote $J_c$ determined after unloading from the data point labeled by the corresponding unprimed letter. Magnetic field was parallel to the tape surface.

FIG. 2. Micrograph of sample 1, showing a series of cracks transverse to the Bi$_2$Sr$_2$Ca$_2$Cu$_3$O$_{10+x}$ core after the conductor had been strained 1% at 4.2 K.

The extrinsic nature of the effect is fortunate since it affords the possibility of improving $\varepsilon_{\text{rev}}$ through different processing. Indeed, one method for enhancing the mechanical properties is to subdivide the superconducting material into fine filaments and embed them in a ductile matrix to fill crack initiation sites at the surface of the filament.
