ABSTRACT. The local collection characteristics of grain interiors and grain boundaries in thin film CdTe polycrystalline solar cells are investigated using scanning photocurrent microscopy. The carriers are locally generated by light injected through a small aperture (50-300 nm) of a near-field scanning optical microscope in an illumination mode. Possible influence of rough surface topography on light coupling is examined and eliminated by sculpting smooth wedges on the granular CdTe surface. By varying the wavelength of light, nanoscale spatial variations in external quantum efficiency are mapped. We find that the grain boundaries (GBs) are better current collectors than the grain interiors (GIs). The increased collection efficiency is caused by two distinct effects associated with the material composition of GBs. First, GBs are charged, and the corresponding built-in field facilitates the separation and the extraction of the photogenerated carriers. Second, the GB regions generate more photocurrent at long wavelength corresponding to the band edge, which can be caused by a smaller local band gap. Resolving carrier collection with nanoscale resolution in solar cell materials is crucial for optimizing the polycrystalline device performance through appropriate thermal processing and passivation of defect and surfaces.
Effective, high-efficiency and low-cost photovoltaics represent the “holy grail” technology to successfully eliminate our dependence on fossil fuels. Thin-film polycrystalline materials are attractive for manufacturing of low-cost PV modules, but improvements in efficiency are still required to ensure cost competitiveness. In particular, CdTe/CdS heterojunction solar cells are the leading technology in the thin-film PV market today. This success is primarily based on the inherently simple and low-cost deposition method used to produce these modules with manufacturing cost as low as $0.6/W.\textsuperscript{1,2}

Despite having similar optical properties, polycrystalline thin-film CdTe devices consistently show lower $V_{oc}$ when compared, for example, to GaAs single crystal solar cells which hold a record $V_{oc} = 1.122$ V\textsuperscript{2} (for both direct bandgap materials $E_g = 1.4$ eV and absorption coefficient $\alpha \approx 3.0 \times 10^4$ cm\textsuperscript{-1} to $9.0 \times 10^4$ cm\textsuperscript{-1} at 650 nm). This lower performance is primarily caused by the high-density of non-radiative recombination centers within polycrystalline CdTe. The $V_{oc}$ of the best CdTe solar cells is currently limited at 0.86 V, which is considerably below the theoretical predictions\textsuperscript{3,4}, leading to an efficiency of 18.7 %.\textsuperscript{2,4} For large area modules, the current $V_{oc}$ record is 0.90 V, with an efficiency record of 16.1 % under global AM1.5 illumination.\textsuperscript{5}

The polycrystalline CdTe absorber layer in a PV device is composed of grains $\approx 1$ $\mu$m in diameter, as shown by the scanning electron microscopy (SEM) image for a $p$-type CdTe layer in Fig 1(a) and Figure SOM-1. It is not surprising that the properties of the grain interiors (GIs) can be quite different from those of the grain boundaries (GBs). The GBs accumulate microscopic defects, such as dislocations, vacancies, and distorted bonds, which can strongly affect the transport properties of both majority and minority carriers. Figure 1(b) shows an atomic resolution transmission electron microscopy (TEM) image of a sharp interface between two CdTe grains, which have been shown to introduce electronic states within the band gap and,
consequently, significant trap-assisted recombination and/or band bending. Recently, it has been shown that during the conventional CdCl$_2$ chemical treatment used to improve the devices Cl atoms replace Te which also leads to local band bending. For a $p$-type material, these gap states (or ‘trap states’) are spatially localized and trap holes, resulting in an accumulation of positive charges $p$ at the boundaries (as represented in Fig SOM-2).

The highest $V_{oc}$ reported for CdTe solar cells, 0.86 V to 0.91 V, was achieved by using single-crystalline $p$-CdTe, instead of a polycrystalline layer. The significant lowering of $[qV_{oc}]$ in polycrystalline CdTe is caused by a leakage (or shunt) current when a PV diode is forward biased (e.g. Fig. 1(c)), which can be partially associated with the device micro/nanostructure and the presence of the GBs. Therefore, measuring the electrical properties of the GBs and the GIs exposed to different chemical treatments that passivate the CdTe layer has been the emphasis of multiple studies aiming to increase $V_{oc}$ (>$1.0$ V) and improve device performance. Here, we focus on mapping the local electrical characteristics of the GIs and GBs by spatially and spectrally resolving the generated photocurrent and the external quantum efficiency (EQE) in the semiconductor material with nanoscale resolution. For that, we use near-field scanning optical microscopy (NSOM) probes as a local source of illumination/excitation.

To date, scanning probe microscopy techniques have been extensively used to map structural and electrical properties of polycrystalline solar cells. In particular, atomic force microscopy (AFM) and scanning tunneling microscopy (STM), have been used to explain the beneficial role of the GBs in CdTe solar cells for photocurrent collection, which is attributed to both the build-in electric fields and composition variations within the polycrystalline grains. Further, NSOM fiber-based apertured probes have allowed the identification of relative changes in local photoresponse of solar cells by means of scanning photocurrent
microscopy\textsuperscript{30 31 32 33}, which is particularly useful for characterizing inhomogeneous materials, such as organic and thin-film polycrystalline solar cells.

Here, we use scanning photocurrent microscopy (SPCM) to image the local electronic properties of CdTe solar cells. We spatially and spectrally resolve the photocurrent distribution and the EQE within the CdTe polycrystalline layer of the solar cell while mimicking the power density operation conditions of real devices. Possible topography effects are addressed by sculpting shallow-angle wedges on the originally rough CdTe grains. The use of the wedge geometry also offers a pathway for spectroscopic photocurrent tomography of the device through assembling and quantifying photocurrent maps at different wavelengths and absorber thickness. We find that the GBs are consistently better current collectors compared to GIs. At short wavelengths (< 600 nm), when light is absorbed near the exposed surface, the EQE is relatively small because of surface recombination. However, we find that the GBs significantly outperform the GIs due to built-in field facilitating the separation and extraction of electrons and holes. This result also suggests that non-radiative recombination at well-passivated GBs is relatively small. Close to the material bandgap (860 nm) the EQE enhancement at the GBs is found to be ×1.5. The latter effect can be attributed to the higher absorption at the GBs due to smaller bandgap caused by compositional variations.

RESULTS and DISCUSSION

Figure 2 shows (a) topography and (b) photocurrent maps of a representative region of the CdTe solar cell. The experimental set-up used for the nanoscale SPCM measurements is described in details in the Methods session and Figure SOM-3. During the scan, the light source (532 nm) was successively turned ‘on’ and ‘off’ to confirm that the photocurrent signal was
being exclusively generated by the local excitation source (NSOM probe), as indicated by the line scan profiles of Figure 2(c-e). The line profiles of topography and photocurrent displayed in Fig 2(e) are anti-correlated. Since GBs appear as topographical depressions in line scans, the result in Fig. 2(e) illustrates that the GBs are better photocurrent collectors than the GIs. The noise level of the current signal in the dark (Fig. 2(d)) was used to infer the uncertainty of the photocurrent measurements, which is ≈1.3 pA. The listed light power is the power emitted by the NSOM probe, and in all cases it corresponds to a low injection level, mimicking realistic conditions of solar cells’ operation. Because the CdTe layer does not contain an anti-reflection coating, we expect at least 30% of the light to be reflected, and not absorbed.

We note that the as-prepared CdTe surface is topographically rough, which can complicate interpretation of SPCM measurements. To examine the possible influence of topography on the photogenerated current signal, a wedge with ≈5° angle was sculpted by focused ion beam (FIB) on the surface of the CdTe grains, as shown in Figure 3(a). Low beam current (1.0 nA) was used to minimize the surface damage and to preserve the crystalline property of the material, as seen in Figure 3(b). Electron back-scattering diffraction (EBSD) measurements of the wedge and of the as-grown adjacent regions presented similar distributions of the grain orientations, confirming that the wedge did not modify the polycrystalline nature of the sample, as desired – see Figure SOM-4. The wedge line profile has a residual roughness associated with the ‘curtain effect’ produced by the ion beam of ≈0.2 μm, in contrast with the original grain roughness of (≈1.0 μm) uncorrelated with the local grain structure, as displayed in Fig 3(c). Despite the modified topography of the grains, the photocurrent of the device showed a non-uniform current distribution (Figure 3(d)), in accordance with the measurements performed on the unmodified
grains. These measurements further confirm that the photocurrent is not strongly affected by the topography and that the GBs are indeed more efficient current collectors compared to the GIs.

The spectrally–resolved SPCM measurements on the same region of the specimen allow us to probe different volumes of the device, in accordance with the absorption coefficient $\alpha$ of CdTe (Figure 4(a)), and to create a tomographic map of the photocurrent. Figure 4(b) illustrates the sampled volume of the CdTe device at different excitation wavelengths. The nanoscale spatially resolved photocurrent maps were acquired by controlling the power and the wavelength of the incoming light through the NSOM probe. For that, a supercontinuum laser source and appropriate filters were used, as explained in details in the Methods session. For all nanoscale SPCM measurements, the topography signal was simultaneously acquired (Figure 4(c)). At short wavelengths ($\lambda = 532$ nm, Figure 4(d)), most of the light is absorbed within the first 100 nm of the exposed material. The overall spatial contrast is similar to that presented in Fig. 2, with the GBs showing higher collection efficiency. The photocurrent is generated far from the $p$-$n$ junction and is likely limited by the surface recombination processes and by the recombination within the CdTe layer. For longer wavelengths (Figure 4 (e)-(f)), $\lambda = 600$-$800$ nm), the volume closer to the $p$-$n$ junction is excited and the overall photocurrent is increased. However, the signal is averaged over a larger excitation volume, and the contrast between the GBs and the GIs is diminished.

Unexpectedly, at excitation wavelengths close to the bandgap energy of CdTe ($E_g = 1.44$ eV, $\lambda = 860$ nm), the contrast between the GBs and the GIs is increasing again even though the excitation volume grows larger. At this wavelength, $\alpha = 1.3$ cm$^{-1}$ for CdTe. At energies below the band gap (Figures 4(h)-(i)) the absorption quickly vanishes (Fig. 4(a)) resulting in a
significant reduction of the generated photocurrent. The contrast between GBs and GIs, however, remains strong. This sharp contrast may be caused by stoichiometry variations at the GBs resulting in smaller band gap and, therefore, in higher absorption; however, the accurate and unambiguous determination of the chemical composition of the GBs requires the use of high-resolution destructive techniques, such as atom probe tomography.\textsuperscript{34}

One of the primary figures of merit of a PV device is the EQE, defined as the number of charge carriers produced by the solar cell per photons incident on the device. Macroscale measurements of EQE are valuable to diagnose how effectively the device is converting sunlight into electricity along the spectrum. Nevertheless, for inhomogeneous materials such as CdTe, the contribution of GBs and GIs to the EQE can strongly depend on variations in composition and on the transport properties found within the different grains and interfaces. Here, we use the nanoscale SPCM measurements to spatially resolve the EQE of the CdTe GBs and GIs, which is defined according to the following equation:

\[
EQE = \left(\frac{hc}{q}\right) \frac{1}{\lambda} \frac{I}{P} \tag{1}
\]

Where \(h\) is Plank’s constant, \(c\) is the speed of light in vacuum, \(q\) is the electronic charge, \(\lambda\) is the excitation wavelength, \(I\) is the generated photocurrent, and \(P\) is the incident power, or photon flux. The generated current \(I\) and the incident power \(P\) are determined directly from the photocurrent measurements and power source calibration, respectively.

In order to characterize the collection characteristics of the CdTe layer, we spatially and spectrally map the EQE of the GBs, GIs and the grain sides (GSs) over a broad region of the spectrum, as shown in Figures 5 and SOM-5. The GSs have a topography distinct from GIs.
caused by the remarkable height variation of the CdTe grains. The EQE map for \( \lambda = 850 \) nm displayed in Figure 5(a) show significant spatial variations. The average EQE (Fig. 5(b), grey solid line) was determined by integrating over the scanned area of 10 x 10 \( \mu m^2 \). At short wavelengths (\( \approx 500 \) nm) the GBs demonstrate nearly two-fold enhancement in collection efficiency when compared to the average EQE for the scanned area. The average EQE is limited by surface and bulk recombination as light is absorbed far from the \( p-n \) junction of the device. For 600 nm to 750 nm, the EQE is steadily increasing, reaching \( \approx 30 \% \) with no significant difference between the GBs, the GSs and the GIs. The contrast between the GIs, as well as GSs, and GBs emerges again near 800 nm, and remains nearly unchanged even as the EQE rapidly diminishes at the bend edge.

In general, there are two main contributing processes that must be taken into account in analyzing the SPCM measurements. The first process is the light absorption and carrier generation, which varies as a function of the wavelength of the incident light. The absorption volume increases at longer wavelengths with a sharp increase at the wavelength corresponding to the band edge. The second process is related to carrier recombination. Recombination losses can be very different near the exposed surface (surface recombination), neutral region of CdTe absorber, depletion region and near the metallurgical \( p-n \) junction. The photocurrent contrast between GSs and GIs at different wavelengths can originate from different contributions. The GS and GI most likely share similar chemical composition, but different topography. The contrast in the current signal behaves alike the GIs; no significant difference was found between these two situations. The relative EQE enhancement (defined here as the enhancement over the spatial average) at the GBs for short wavelengths (\( \lambda < 600 \) nm, Figure 5(c)) is likely a direct consequence of the local built-in electric field facilitating the carrier separation and, therefore,
competing with the recombination (both recombination in “neutral” region of CdTe and surface recombination). This mechanism of the enhancement of photocurrent at the GBs has been reported and discussed in electron-beam induced current experiments and in previous NSOM experiments. For 600 nm < \lambda < 800 nm, the difference between light injection to the GBs and GIs and GSs is insignificant. There, the excitation volume is larger and the contrast averages out. Close to the CdTe bandgap, despite an even larger excitation volume, light injection at the GBs results in a larger photocurrent, and the EQE is enhanced at the boundaries by \approx 50\%. The contrast enhancement is clearly associated with proximity of the excitation energy to the band gap: the onset of the contrast enhancement as a function of the wavelength is rather sharp, and the contrast remains strong even as the overall photocurrent decreases significantly at longer wavelengths. We suggest that the measured photocurrent enhancement at GBs in this wavelength range is caused by an increase in absorption relative to the GIs. This means that the band gap at GBs is effectively smaller due to accumulation of impurities and defects, as previously suggested by Smith et al. As expected, beyond the material bandgap (\lambda > 860 nm) the EQE decays rapidly, and the light-generated photocurrent can be eventually associated with trap stated within the CdTe band gap.

The strong contrast of the photocurrent enhancement at the GBs and its peculiar dependence on the excitation wavelength allowed us to identify two distinct mechanisms for the observed enhancement. In general, a meaningful comparison of photocurrent maps measured at different wavelength is a complicated problem. On one hand, local spectroscopic measurements could be sensitive to the variation of composition and spatial distribution of electronic states such as defects and traps. However, at the same time the sampled volume is changing in accordance with the absorption coefficient, affecting the averaging and the spatial resolution. Additionally, in a
PV device, both the recombination and the collection efficiencies vary strongly with the penetration depth toward the p-n junction. Shaping a thin-film PV device in a wedge structure as described above, by gradually varying the thickness of absorber and the distance between the surface and the p-n junction, can offer more opportunities for a three-dimensional spectroscopic tomography of different volumes and interfaces of PV devices with high spatial resolution. For example, the spatial resolution at \( \lambda = 532 \text{ nm} \) is limited by the absorption length at \( \approx 100 \text{ nm} \), and the SPCM measurements of thinner areas of the wedge can enable high-resolution mapping of properties within the depletion region and close to the metallurgical p-n junction (see Figure SOM-6). Such measurements can help identify the recombination and leakage mechanism related to material inhomogeneity that currently limits the \( V_{oc} \) in thin-film PV materials. We have observed that for a short wavelength (e.g. \( \lambda = 532 \text{ nm} \)), the spatially averaged EQE increases descending down the wedge. This is expected since the generation volume is approaching the depletion region with higher collection efficiency. Correspondingly, the maximum in EQE shifts to shorter wavelengths (see Figure SOM-6). However, further study is needed to more quantitatively relate the spatial variation of the SPCM signal with specimen thickness and determine effects of the wedge fabrication on surface recombination.

**CONCLUSIONS**

Summarizing, we mapped and quantified the photocurrent generated by CdTe/CdS solar cells GBs and GIs under different illumination conditions by means of nanoscale-resolved SPCM. CdTe wedges were milled and measured to exclude possible artifacts caused by surface topography on coupling of the near-field localized light source. A photocurrent tomography of the CdTe layer was built by spectrally resolving the light-generated current, which consistently
showed that the GBs are more efficient current collectors compared to GIs. The nanoscale resolution maps of the EQE inferred from the photocurrent scans revealed that at short wavelengths ($\lambda < 600$ nm) the GBs outperform the GIs by more than a factor of two, independent of the grain orientation. Surprisingly, close to the material bandgap the difference in EQE was less than 1.5.

We further demonstrated that SPCM of the sample in wedge geometry can be used to probe the photoelectronic properties of critical device volumes such as depletion region and $p$-$n$ junction with high-spatial resolution. EQE variation at these interfaces helps identify the mechanisms, which limit thin-film PV device efficiency.

METHODS

**Sample preparation:** The commercially available CdTe solar cells used in this study are formed by the following layers (from top to bottom): 4.0 mm of glass substrate, 550 nm of bilayer transparent conductive oxide (TCO), 50 nm of $n$-type CdS, and 3.5 μm of $p$-type CdTe – see Figure SOM-1. Holes ($p$) and electrons ($n$) are majority and minority carriers, respectively. All samples were submitted to CdCl$_2$ treatment. The grains composing the CdTe layer (3.5 μm thick) are 1 μm to 2 μm in size with no preferential crystallographic orientation.$^{17}$ The original back contact was manually removed by peeling it off of the CdTe layer. No anti-reflection coating was added. 100 nm thick platinum pads were evaporated through stencil masks, and used as top contacts.

**Electrical measurements:** Dark I-V curves were obtained by contacting the top and the bottom of the solar cells using tungsten probes in a conventional probe station. A voltage sweep from -0.5 V to + 2.0 V was applied to the device, using steps of 0.1 V per second.
**Photocurrent imaging:** Topography and photocurrent were acquired simultaneously using a XYZ-piezo stage with Z feedback control, where the average distance between the sample surface and the probe was ~ 10 nm for all measurements. To vary the incident light wavelength, either an optical parametric oscillator (OPO) laser or a supercontinuum laser with the appropriate combination of band-pass filters (10 nm bandwidth) and neutral density filters were used, see schematic of experimental set-up in Figure SOM-3. The sub-wavelength NSOM probes used in this work were tapered optical fiber probes mounted on a tuning fork with 200 nm to 300 nm core aperture within a (20 nm) Cr / (200 nm) Au cladding, force constant ~15 N/m and resonance frequency ≈ 150 kHz. Nanoscale spatial resolution was achieved by placing the tapered fiber probes close to the surface of the grains, therefore providing a local source of excitation. Because of the superstrate geometry of the devices, light was injected in the exposed p-doped CdTe grains. Because this layer does not have an anti-reflection coating, we expect at least 30% of the incident light to be reflected. The NSOM tip was positioned off the edge of Pt contact (< 10 μm), see SOM-3. The removal of the original back contact metallization by manually peeling the layer off allowed for the tip placement in a closer proximity to the CdTe surface to improve the spatial resolution. Thus, the resolution was primarily determined by the probe diameter and the materials’ absorption coefficient α, as explained in the text. The photocurrent signal was amplified by a low-noise variable gain amplifier operating at $10^7$ V/A to $10^9$ V/A gain.

The laser power was calibrated after transmission through the NSOM probes at both near and far field. The power in near-field can be different because of tip-sample interaction affecting the light coupling. For that, a Si photodetector pre-calibrated for the different wavelengths was placed in the location of the sample, and the probe was approached to mimic the conditions of
the SCPM measurements. The power quoted in all captions refers to the power of the laser incident into the sample.
