Abstract

Cyber-attacks on the system supporting an enterprise's mission can impact achieving its objectives. We describe a layered graphical model as an extension of a forensic investigation in order to quantify mission impacts. Our model has three layers: the upper layer models operational tasks that constitute the mission and their inter-dependencies. The middle layer reconstructs attack scenarios from available evidence to reconstruct their inter-relationships. In cases where not all evidence is available, the lower level reconstructs potentially missing attack steps. Using the three levels of graphs constructed in these steps, we present a method to compute the impacts of attack activities on missions. We use NIST's National Vulnerability Database's (NVD)-Common Vulnerability Scoring System (CVSS) scores or forensic investigators' estimates in our impact computation. We present a case study to show the utility of our model.

Keywords: Mission attack impact, Enterprise infrastructure, Cloud forensic analysis, Layered-graphical model

1 Introduction

Organizational missions are used to abstract activities envisioned by organizations, usually defined at the high-level as a collection of business processes. Cyber-attacks on an enterprise infrastructure that support such missions can impact these missions. Concurrently, a growing number of organizational business processes and services are now hosted on cloud operators' data centers. Given that most networked infrastructures including cloud services are supported by hardware and software assets, any attack that impacts these assets could impact the missions they support. Therefore, analyzing and quantifying the mission impacts of cyber-attacks is of importance to infrastructure system planners in migrating security threats and improving mission resilience, which is the primary objective in this paper.

NIST's NVD-CVSS provides impact estimates of exploitable vulnerabilities on IT systems [2]. Other publications use NIST's NVD-CVSS to predict the impacts of multi-step attacks on assets by considering constructing all possible attack paths [1, 5, 6]. However, evaluating all paths is infeasible for forensic analysis to assess damages due to the large number of paths and vulnerabilities. Additionally, quoted publications only consider the vulnerabilities reported publicly, not including zero-day attacks.

Because post-attack artifacts obtained during forensic investigations provide information that can be used to analyze attacks, we create a layered graphical model that uses this information to quantify the attacks' impacts on missions. Our model has three layers. The upper layer models operational tasks that constitute the mission and their inter-dependencies, where a mission is modeled as a collection of choreographed tasks. The middle layer collects evidence from intrusion detection system (IDS) tools and event logs to reconstruct attack scenarios. In cases where not all evidence is available, the lower layer reconstructs potentially missing attack steps using system calls that were executed to fulfill the mission. Finally, the two mapping algorithms integrate the information obtained from the three layers to ascertain how the mission execution was supported midst attack activities. Using the layers of graph-like dependency information, our model provides a method to compute impacts of attacks on missions using the NIST NVD-CVSS scores or forensic investigators' estimates on attacks toward the underlying software or hardware. We present a case study to show the utility of our model, and how it can be used to migrate attack risks in a networked infrastructure. To the best of our knowledge, there isn't an integrated forensic analysis framework that quantifies the mission impacts of multi-step attacks in a complex enterprise infrastructure which uses cloud-based services.

The rest of the paper is organized as follows. Section 2 discusses background and related work. Section 3 presents the three-layered graphical model. Section 4 uses a case study to show how the model computes mission impacts of attacks in a cloud environment, and discusses how the impact analysis can be used to enhance a networked infrastructure. Section 5 gives the conclusion.

2 Background and Related Work

We present the background and related work in this section.

2.1 Cloud Forensics

NIST defined Software-as-a-Service (SaaS), Platform-as-a-Service (PaaS) and Infrastructure-as-a-Service (IaaS) as deployment models [3]. SaaS allows clients to use providers' applications running on a cloud infrastructure. PaaS allows clients to deploy on the cloud client applications using programming languages, libraries, services and tools supported by the provider. IaaS provides clients with the capability of provisioning processing, storage, networks and other fundamental computing resources, so that the clients can deploy and run software including operating systems and applications.

Digital forensic investigators seek attack evidence from computers and networks. According to Ruan et al., cloud forensics is a subset of network forensics that follows the main phases of network forensics with techniques tailored to cloud computing environments [4]. For example, data acquisition is different in SaaS and IaaS, because the investigator will have to solely depend on cloud service providers in SaaS. Investigators can acquire the virtual machine images from IaaS customers.

2.2 Related Work

Attackers tend to use multi-step, multi-stage attacks to impact important services protected using complex mechanisms. Researchers have proposed and designed models to estimate the mission impacts of such attacks by considering all known vulnerabilities. Sun et al. proposed using a multi-layered impact evaluation model to estimate the mission impacts [10]. In this model, a lower vulnerability layer is proposed to map to an asset layer, and then to a service layer, which finally maps to the mission layer, so that the mission impacts can be calculated by using vulnerabilities' CVSS scores and the relationships between missions to the lower level vulnerabilities. However, this model does not provide a method to construct the attack paths. Another group of researchers, Sun et al., combined mission dependency graphs with attack graphs generated by an attack graph generation tool, MulVAL [11], to estimate the attack mission impacts in the clouds [6]. Noel et al. designed a cyber-mission impact assessment framework by leveraging Business Process Modeling Notation (BPMN) and their attack graph generation tool named Topological Vulnerability Analysis (TVA) [12] that combines an exploit knowledge base and a remote network scanner, analyzing all potential attack paths leading to attack goals to evaluate potential mission impacts [5, 6]. However, these approaches use vulnerabilities collected from the bug-report community such as NIST's NVD to assess the impacts of attacks. These do not scale to large infrastructures or zero-day attacks.

Forensics researchers have reasoned on post-attack evidence using correlation rules to reconstruct

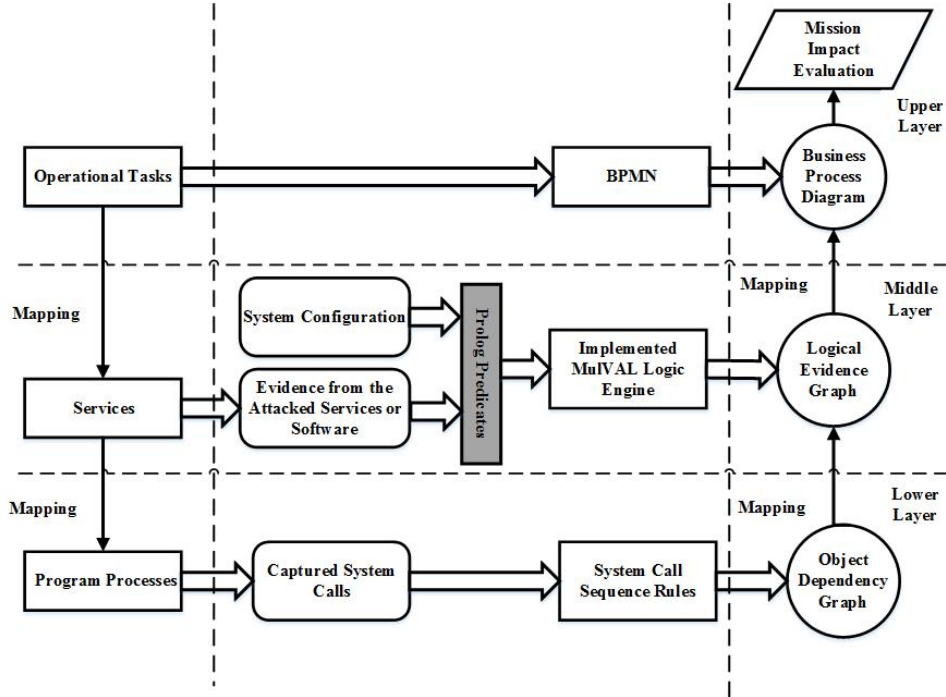

Figure 1: The three-layered graph model for mission impact evaluation

the attack scenarios. The objective of this work has been to reconstruct criminal or unauthorized actions shown to be disruptive to missions [7, 13]. To reconstruct attack scenarios that have legal standing, we integrated a Prolog logic tool, MulVAL, with two databases, including a vulnerability database and an anti-forensic database, to ascertain the admissibility of evidence and explain missing evidence due to attackers’ using anti-forensics [9]. We also expanded this work by using system calls to reconstruct the missing attack steps due to missing evidence in the higher application level, and using Bayesian Network to estimate the experts’ belief on the reconstructed attack scenarios [14]. However, no work exists to estimate the mission impacts of attacks launched toward an enterprise’s infrastructure.

3 Our Three-layered Graphical Model

Figure 1 shows our model. The lower layers reconstruct attack paths so that the attacks can be mapped to tasks and missions in the upper layer for mission impact computation.

3.1 The Upper Layer

The upper layer models tasks and missions as business processes. We model business processes using a Business Process Diagram (BPD) using the Business Process Modeling Notation (BPMN). We use tasks, events, sequencing, exclusive choice, parallel gateways, message flows and pools [16] to construct BPDs formalized in Definition 1 (Originally defined in [16]).

Definition 1 *Business Process Diagram-BPD:*

Any quintuple $(Pool, T, E, C, OP)$ satisfying the following conditions are said to be a BPD.

- Let T be a set of tasks and E be a set of events.
- Let E^{send}, E^{rec} be two disjoint subsets of E and $e_{start}, e_{end} \in E$ be two events we refer to as start and end events. Hence, $E = e_{start} \cup e_{end} \cup E^{send} \cup E^{rec}$ are respectively called start, stop, message sending, message receiving events.
- $T^{com} = \{(t, e_{send}, c), (t, e_{rec}, c) : t \in T, e_{send} \in E^{send}, e_{rec} \in E^{rec}, c \in C\}$ are said to be the set of communicating tasks.
- $OP = \{F, M, XOR, ;\}$ called parallel fork, parallel merge, exclusive choice and sequencing.
- C is a set of channels.

Business processlets and a Business Process are defined as follows.

- Any $t \in T \cup T^{com}$ is said to be a processlet.
- If P and Q are processlets, then so are $P; Q, F(P, Q)M$ and $P(XOR)Q$.
- If $P \in T \setminus T^{com}$ and e_{start}, e_{end} are start and end events, then $e_{start}; P; e_{end}$ is said to be a business process.
- Pools are business processes with the constrains: for two pools P_1 and P_2 , there is a task (t_1, e_{send}, c) in P_1 if and only if there will be another task (t_2, e_{rec}, c) in P_2 , so that the message can be passed through channel c .

3.2 The Middle Layer

The middle layer constructs potential attacks from evidence available from system logs and IDS alerts. Our objective is to map these attack scenarios to missions modeled as BPDs. Because we only consider attack scenarios substantiated using available evidence, the created attack paths do not include all possible attack paths and vulnerabilities. However, sometimes, not all evidence may be available in IDS logs, which will be addressed in the lower layer.

We reconstruct attack scenarios by using a forensic analysis tool created in our previous work [7]. This tool uses rules to create directed graphs of available items of evidence and correlate them together as witnesses of attacks. Because rules are used to create these graphs, they are called logical evidence graphs (LEGs) formalized in Definition 2, originally defined in [7].

Definition 2 *Logical Evidence Graph-LEG:*

A $LEG = (N_r, N_f, N_c, E, L, G)$ is said to be a logical evidence graph (LEG), where N_f, N_r and N_c are three sets of disjoint nodes called fact, rule, and consequence fact nodes respectively. $E \subseteq N_f \cup N_c \times N_r \cup (N_r \times N_c)$, L is the mapping from a node to its labels and $G \subseteq N_c$ are observed attack events. Every rule node has a consequence fact node as its single child and one or more fact or consequence fact nodes from prior attack steps as its parents. The labels of nodes consist of instantiations of rules or sets of predicates specified as follows:

1. A node in N_f is an instantiation of predicates that codify system states including access privileges, network topology consisting of interconnectivity information, or known vulnerabilities associated with host computers in the system. We use the following predicates:
 - (a) $hasAccount(_principal, _host, _account)$, $canAccessFile(_host, _user, _access, _path)$ etc. to model access privileges.
 - (b) $attackerLocated(_host)$ and $hacl(_src, _dst, _prot, _port)$ to model network topology, namely, the attacker's location and network reachability information.
 - (c) $vulExists(_host, _vulID, _program)$ and $vulProperty(_vulID, _range, _consequence)$ to model vulnerabilities exhibited by nodes.
2. A node in N_c represents a predicate that codifies the post attack state as the consequence of an attack step. We use predicates $execCode(_host, _user)$ and $netAccess(_machine, _protocol, _port)$ to model the attacker's capability after an attack step. Valid instantiations of these predicates after an attack will update valid instantiations of the predicates listed in (1).
3. A node in N_r consists of a single rule in the form $p \leftarrow p_1 \wedge p_2, \dots, \wedge p_n$ with p as the child node of N_r is an instantiation of predicates from N_c . All p_i for $i \in \{1 \dots n\}$ as the parent nodes of N_r are the collection of all predicate instantiations of N_f from the current step and N_c from the prior attack step.

Table 1: Dependencies arising out of systems calls

Dependency	Event Description	Unix System Calls
$process \rightarrow file$	Process modifies file	write, pwrite64, rename, mkdir, linkat, link, symlinkat, etc
$file \rightarrow process$	Process reads file	stat64, lstat6e, fsat64, open, read, pread64, execve, etc.
$process \leftrightarrow file$	Process uses/modifies file	open, rename, mount, mmap2, mprotect etc.
$process1 \rightarrow process2$	Process1 creates/terminates Process2	vfork, fork, kill, etc.
$process \rightarrow socket$	process writes socket	write, pwrite64, etc.
$socket \rightarrow process$	process checks/reads socket	fstat64, read, pread64, etc.
$process \leftrightarrow socket$	Process reads/writes/checks socket	mount, connect, accept, bind, sendto, send, sendmsg, etc.
$socket \leftrightarrow socket$	process reads/writes socket	connect, accept, sendto, sendmsg, recvfrom, recvmsg

and *review medical records* that depends on the client's request. The business process in Pool 2 is composed of start/end events, a task *check user request* followed by an exclusive gateway that directs to two tasks *request policy files* and *request customer databases*, which depends on the message passed from the task *send out request* in pool 1. In each of the decision task branch, there is an exclusion decision gateway(named *file available* and *data available* respectively) followed by tasks that either send the data(*policy file* or *customer medical records* through the message passing) back to the clients or reject the customer's requests otherwise. Pool 3 is a business process used to describe IaaS user services, which is mainly composed of three tasks *encrypt data in VM1*, *resize VM2*, and *install and run program in VM2* that are the exclusive decisions of the task *check IaaS user request*. For each of the three business processes in the three pools, we consider the last task(s) before the end event as the business process mission(s).

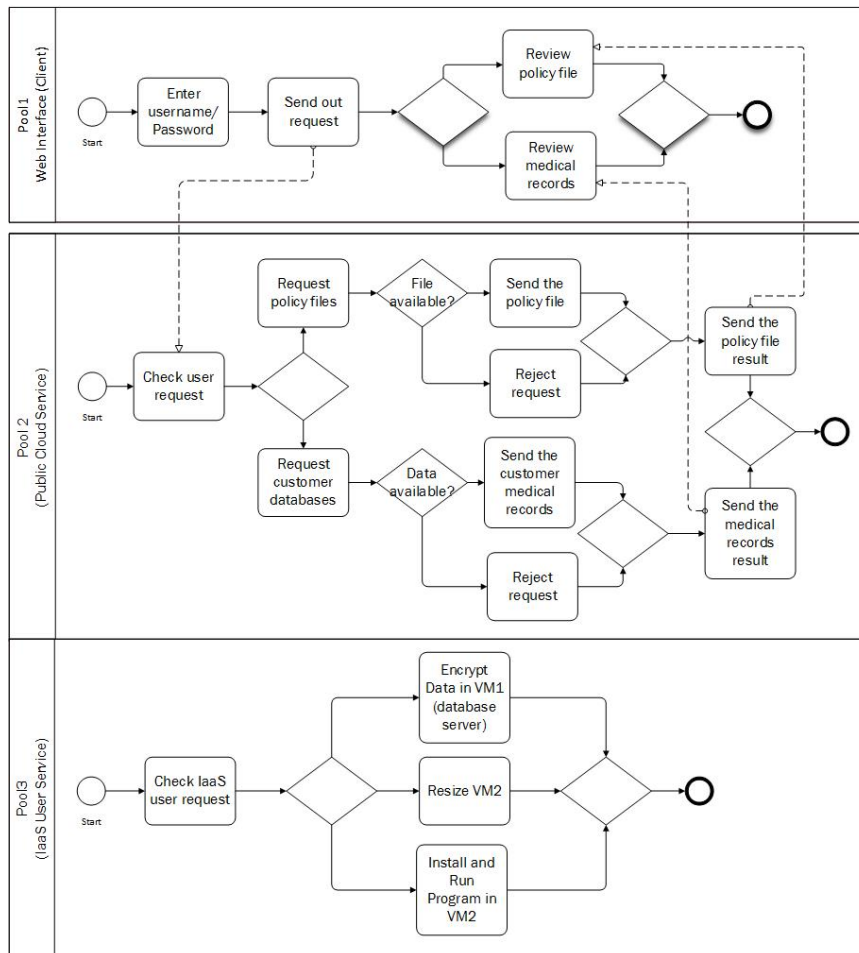

Figure 3: The BPD of the experimental network

2. The Logical Evidence Graph

Table 2 shows evidence of the SQL injection attack with Snort alerts and database access logs. Using timestamps, corresponding alert content and MySQL general query logs, we asserted that the attacker used a typical SQL injection with payload `'1'='1'` to attack the customers' database

Table 2: The snort alert and database server log of SQL injection attack

Time Stamp	Machine	IP Address/Port	Snort Alert and Database Server Access Log
	Attacker	129.174.124.122	
06/13-14:37:27	web server	129.174.124.184	SQL injection attack(CWE-89)
13/Jun/2017:14:37:34	Database server	129.174.124.35	Access from 129.174.124.184

in the database server. Our IDS failed in capturing the DoS attack launched by exploiting the vulnerability CVE-2015-3241 in OpenStack Nova services. Because OpenStack application programming interface (API) logs provide users' operations of running instances (we illustrate some of these API logs in Figure 4, where we use bold font to show the users' operations), we used them to conclude that the IaaS user in VM2 (the attacker in our experiment) kept re-sizing and deleting the instance VM2 that co-resided in the same physical machine as the database server (VM1), which caused the DoS attack toward the database server.

rations and the evidence for the SQL injection attack and DoS attack to Prolog predicates shown in Figures 5, 6. The output LEGs produced by the tool are shown in Figure 7 and Figure 8 respectively with node names in Tables 3, 4. The two LEGs are not grouped together due to distinct attacker locations and privileges. Consider an example attack step (Nodes 3, 7, 8 \rightarrow 2 \rightarrow 1 in Figure 8). Facts of LEGs are shown in Nodes 7, 8, modeling pre-attack configurations and vulnerabilities. The consequence fact node (Node 1) shows post-attack evidence derived by applying a rule (an ellipse Node 2 connecting Nodes 3, 7, 8 to the post attack status, Node 1) to the parent facts (Nodes 7, 8) and parent consequence fact (Node 3 that is obtained from a prior stepping stone step).

3. The Object Dependency Graph

Due to the lack of IDS alerts and logs for the side-channel and social engineering attacks, we could not reconstruct the two attack scenarios in the form of LEGs as we did for the SQL injection and DoS attacks. Therefore, we turned to the corresponding system calls we captured during the attacks and used the method mentioned in Section 3.3 to construct ODGs for a forensic analysis.

Figure 9 and Figure 10 are a fraction of the system calls captured from VM1 (the database server) and VM2 (the attacker’s VM) during the side-channel attack. The system call in Figure 9 shows that a file from VM1 (named *message.txt*) was encrypted by using GnuPG 1.4.12. System calls in Figure 10 show that a probe program *bin/probe* (Line 1) in VM2 used *mmap2* (Line 3)

to force the underlying system to share memory addresses (Lines 5, 6, 7...) with the probing process; hence the probing process could read data from the shared memory addresses between VM1 and VM2 for a later malicious analysis (Lines 10, 11, 12 and Line 1 show the data was written to a file named *out.txt*, and our continuous captured system calls show, later, a Python program was used to extract and analyze the information in *out.txt*). Figure 11 is a fraction of the system calls captured from the file server, where the *read/write* system call trace shows that the *test.txt* in *FileServer* has been modified. Because the corresponding *sshd* log in the *FileServer* recorded the users' access, it was easy to judge that the attacker stole a legitimate user's credentials to modify the policy file (the *sshd* log is omitted).

```
execve("/home/flush-reload-master/build_gpg/gnupg-1.4.12/bin/gpg", ["/home/flush-reload-...", "--yes", "-sign", "message.txt"], [/* 61 vars */]) = 0
brk(0) = 0x942b000
.....
```

12. write(5, "520\n215 3 232\n216 0 490\n216 1 26"..., 4096) = 4096
...
```

Figure 10: Filtered system calls of the side-channel attack from VM2

Using the dependency rules listed in the left column of Table 1 and corresponding analysis on the system calls as shown in Figures 9, 10 and 11, we constructed two ODGs, showing the attacker from VM2 read the shared cache between VM1 and VM2, and the attacker from Internet used a legitimate user's credentials to access the file server and modified a policy file. We mapped both ODGs to the LEGs in Figure 7 and Figure 8. The integrated LEGs show that: (1) the attacker from the Internet launched two attacks including using stolen credentials to modify a policy file and stealing all customers' medical records by using a SQL injection attack; (2) the attacker who was an IaaS user launched two other attacks including a DoS attack and a side-channel attack to the database server.

side-channel attack	CVE-2013-4576	N_{sc}	0.29

4.3 Mission impact computation in our case study

The impact score of each attack step in all LEGs and ODGs is shown in Table 5, where the three impact scores of *CWE-89*, *CVE-2015-3241*, *CVE-2013-4576* were obtained from NIST’s NVD-CVSS and the impact score of the social engineering attack was from our expert knowledge. The impact scores in NIST’s NVD-CVSS are based on a [0, 10] scale, which we converted to a [0,1] interval scale.

We mapped all attacks from LEGs and ODGs to the BPD in Figure 3 and computed the mission impacts of the four attacks as shown in Table 6. Based on Table 6 and the BPD in Figure 3, the cumulative mission impacts are computed and listed in Table 7.

Table 6: The mission impact scores

Pool	Task	Mapping Attack	Weight	Mission Impact
Pool 1	Check username and password	CWE-89	1	$I_1 = 1 \times P(N_1) = 1 \times 0.9 = 0.9$
Pool 2	Data available	CVE-2015-3241	0.9	$I_2 = 0.9 \times P(N_1) = 0.9 \times 0.69 = 0.621$
Pool 2	Request policy files	Social Engineering	1	$I_3 = 1 \times P(N_s) = 1 \times 0.5 = 0.5$
Pool 3	Encrypt data in VM1	CVE-2013-4576	1	$I_4 = 1 \times P(N_{sc}) = 1 \times 0.29 = 0.29$

Table 7: The cumulative mission impact

Pool	Mission	Cumulative Mission Impact
Pool 1	Review policy file	$M = \text{Max}(I_3) = \text{Max}(0.5) = 0.5$
Pool 1	Review medical records	$M = \text{Max}(I_1, I_2) = \text{Max}(0.9, 0.621) = 0.9$
Pool 3	Encrypt data in VM1	$M = \text{Max}(I_4) = \text{Max}(0.29) = 0.29$

4.4 Using mission impacts to reduce attack risks

In a complex infrastructure, different missions use connections and combinations of multiple services. Each service is supported by software and hardware assets that are usually the target of attackers. In such cases, a tool can determine the impacts of cyber-attacks on the missions. By correlating the attacks on lower level assets to the higher level business process diagram and using mission impact scores of those attacks provided by NIST’s NVD-CVSS, our model shows attacks and computes their impacts on complex missions. The information provided by such an analysis can be used by forensic investigators and infrastructure system planners.

As an example, we show how the mission impacts can be used by the system planners to enhance our experimental network. First, the cumulative impact scores in Table 7 show that the attacks on the mission of *review medical records* have a higher impact because the customers’ medical records could be stolen by using a SQL injection attack. This suggests the user input sanitization should be implemented to defeat SQL injections. Second, the attacks and their impact scores shown in Table 6 show the two attacks (a DoS attack and a side-channel attack) were caused by cloud services that have vulnerabilities; hence the corresponding services should be moved to a more stable cloud that has countermeasures to attacks that can be launched through the shared hypervisor or host. Third, Table 6 shows, though the mission impact on the insurance policy stored in the file sever might not be as bad as the SQL injection attack on the database server, it has a score “0.5” that can not be neglected. An easy solution would be limiting the file *write/modify* right to only administrators with local access.

5 Conclusion

We proposed a three-layered graphical model to quantify mission impacts of cyber-attacks in this work. We did so by reconstructing attacks based on available evidence from attack logs and system call sequences when logs missed requisite evidence to reconstruct attack steps. We used impact scores published in the NIST's NVD-CVSS and expert opinions when such numbers are unavailable as a base line to estimate attack impacts. We then mapped the attacks to higher-level business processes and considered their importance weight for business processes to compute the impacts of cyber-attacks on missions. Our case study showed that this model can be used to mitigate the impacts of cyber-attacks in a network. In the future, we will conduct more experiments using attacks on the cloud infrastructure to determine how our framework should be used in order to help enterprises to reduce the security risks of their infrastructures.
